CASE REPORT

Tuberculosis of the Oral Cavity and Associated Structures: The PGIMER Experience

Vidya Rattan, Sachin Rai

ABSTRACT

Extrapulmonary tuberculosis of the oral cavity and its associated structures are diagnostic challenge. It is often misdiagnosed by the attending dentist who is the first among clinicians to come across such pathological entity. Lesions are often slow growing and painless and hence are initially neglected. Tubercular osteomyelitis of the jaw bone is a common occurrence in developing countries like India and often these cases first appear in dental out-patient clinic. The purpose of this paper is to highlight the involvement of oral and maxillofacial structures with few case reports and their concurrent diagnostic procedures.

Keywords: Tuberculosis, Osteomyelitis, Oral cavity.

INTRODUCTION

Tuberculosis (TB) in oral cavity and its associated structures are rare manifestation of extrapulmonary tuberculosis (EPTB), occurring in approximately 3% of all cases. The diagnostic challenge due to its non-specific presentation may mislead the dentist or the clinician and delay the diagnosis. The purpose of this paper is to highlight the variable appearance of EPTB in oral cavity and its associated structures. We also present a pictorial series of few cases involving the soft and the hard tissue of the oral and maxillofacial region which were diagnosed, treated and followed in our unit.

LESIONS OF ORAL CAVITY AND ASSOCIATED SOFT TISSUE STRUCTURES

Common sites for oral tubercular lesions occur are the tongue, palate, gingiva, floor of mouth, soft palate and mucobuccal folds. Tongue is the most common site of involvement and accounts for nearly half of the cases. The clinical presentation in oral cavity may be that of swelling, ulcer or irregular growth which may be single or multiple; ulcerated or non-ulcerated giving a false suspicion of malignancy (Figs 1A and B). TB of the salivary glands is usually secondary to infection of the oral cavity or primary pulmonary tuberculosis. Parotid gland is most commonly involved (Figs 2A and B). Clinical presentation can be acute or chronic. Acute presentation may resemble acute sialadenitis and clinical differentiation may be difficult. Cervical tubercular lymphadenitis may present as multiple matted firm swelling in the neck with a stud collar appearance.

An incisional biopsy or FNAC of the lesion for histopathological examination and microbial culture is mandatory to establish the diagnosis. At times, the histopathological findings may be suggestive of only granulomatous infection. This encompasses a wide range of pathologies rather than definitive TB. Therefore, the clinicians must rely upon the clinical and radiological appearance as evidence to diagnose EPTB.

LESIONS OF THE JAW BONES

The clinical presentation of a patient with jaw involvement with TB may range from painless jaw swelling (lumpy jaw)
Tuberculosis of the Oral Cavity and Associated Structures: The PGIMER experience

Tubercular osteomyelitis of the mandible causes slow necrosis of the bone and may involve the entire mandible. The first demonstrable change is a small translucent area due to decalcification and blurring of trabecular details with irregular areas of radiolucency. The lesion is clinically undetectable at this stage. There is erosion of the cortex with little tendency to repair. Gradually, the bone is replaced by soft tuberculous granulation tissue. Caseation appears at places followed by softening and liquefaction. A subperiosteal abscess (lumpy jaw) then forms presenting as a painless, soft swelling (Figs 3A and B).

LESIONS OF THE TEMPOROMANDIBULAR JOINT

Primary TB of the Temporomandibular Joint (TMJ) is rare. Most of these patients present with preauricular swelling and trismus (Figs 4A and B). The clinical and radiological appearance of TB of the TMJ is non-specific and may be similar to that of arthritis, osteomyelitis or chronic joint diseases. The most common symptom is a painful preauricular swelling (unresponsive to antibiotics), associated with trismus. Radiographs and computed tomography (CT) scans show destruction of parts of the condyle and soft tissue masses. Radiological imaging, biopsy and culture usually confirm the diagnosis of a TB infection.

DISCUSSION

EPTB is an uncommon form of chronic infection which does not present with the typical signs and symptom of pulmonary tuberculosis. Its diagnosis is often overlooked because it has no specific pathognomonic signs. It usually affects organs with suboptimal conditions for bacillary growth and hence has an insidious presentation and a slow evolution. These infections generally involve the head and neck through hematogenous or lymphatic routes. Orofacial tuberculosis is an uncommon form and presents at different sites, such as gingival, tongue, faucial pillars, muscles of mastication and buccal mucosa. EPTB also manifests as tubercular osteomyelitis of the jaw and TMJ.

In a recent classification proposed by Andrade et al, the orofacial tubercular lesion has been subclassified into five...
The mandible and the attached musculature are more affected. The lesion is seen to involve the outer cortical plates, whereas the medullary bone is less affected. Spread through blood vessels supplying the medial pterygoid and masseter muscles is considered the most important in the involvement of the mandibular ramus and body.

Radiologically, tubercular osteomyelitis resembles non-specific osteomyelitis. Differential diagnosis includes actinomycosis lesion and other fungal infections. It has been suggested that MRI assessment improves the clinician’s ability to make a differential diagnosis. MRI features of a TB infection in the TMJ may include synovitis, effusion, bone resorption, and the presence of an abscess. If the condition is misdiagnosed as a common TMJ arthralgia or osteoarthritis, the joint destruction continues. The functional prognosis of the joint depends on the degree of destruction at the time of the correct diagnosis and start of treatment.

Tuberculous osteomyelitis of midfacial bones is extremely rare. Because of its rarity and variable presentation, this condition is difficult to diagnose, unless a high index of suspicion is kept in mind, which is more likely in an endemic area. Tuberculous osteomyelitis of skull bones accounts for 0.1 to 3.7% of all cases of skeletal tuberculosis. Three quarters of such cases are seen in patients less than 20 years of age, and half in those less than 10 years. The condition is usually secondary to a primary focus elsewhere, mainly in the lungs. Direct spread of infection from neighboring structures, such as the orbit, paranasal sinuses, face and nasal mucosa has also been implicated.

CONCLUSION

In a tuberculosis-prevalent country, such as India, it is important to be aware of tubercular lesions involving the orofacial region. A long standing chronic lesion like ulcer, swelling or draining sinus in or around the oral cavity should raise suspicion of TB in the clinician’s mind. Clinical
presentation of EPTB is atypical. Especially when the disease involves obscure occult sites, EPTB may not even be considered in the initial list of differential diagnosis. Incisional biopsy for easily accessible sites and FNAC for deep-seated lesion can help the diagnosis. A histopathological examination and microbial culture should be promptly undertaken. Similarly, TB maybe suspected in situations where a routine therapy fails to bring about an improvement in the lesions. If diagnosed early, chemotherapy will cure the lesion and mutilating surgery can be avoided.
